**Background:** Radiation pneumonitis (RP) is a common complication of thoracic radiation which affects patients' ability to breathe, limits the deliverable intensity of radiotherapy and impairs clinical outcomes, indicating the need for timely diagnosis and management. The purpose of this study was to determine the predictive capability of two peripheral inflammatory cells for RP. **Materials and Methods:** A murine RP model was established using SD rats that received a single dose of 20 Gy thoracic radiation. At 2 and 4 weeks post-radiation, mice were processed to harvest lungs for hematoxylin-eosin (HE) staining and collect blood for flow cytometry analysis. **Results:** By 2 weeks post-radiation, histopathological changes had occurred in the lungs indicating the onset of RP. Peripheral CD45<sup>+</sup>HIS48<sup>+</sup> granulocytes were significantly increased by the radiation treatment at both the early and later time points ( $P < 0.05$ ). However, we did not observe a statistically significant increase of CD45<sup>+</sup>CD11b/c<sup>+</sup>HIS48<sup>-</sup> monocytes/macrophages. **Conclusion:** Our study highlights the possibility that increased levels of peripheral CD45<sup>+</sup>HIS48<sup>+</sup> granulocytes could serve as a predictive indicator of RP. Early detection provides the opportunity for early intervention and therefore, a reduction in the rate and extent of RP.

**Keywords:** Radiation pneumonitis, granulocytes, monocytes/macrophages, peripheral, prediction.

## INTRODUCTION

Radiation pneumonitis (RP), an acute immune inflammation, is a common and clinically significant toxicity associated with thoracic irradiation<sup>(1)</sup>. It develops in 15-40% of patients within 6 to 12 weeks of irradiation<sup>(2-6)</sup>, with the main symptom being fever, cough, respiratory dysfunction, chest pain and, rarely, mortality. Without timely interventions such as high-dose glucocorticoid therapy<sup>(7,8)</sup> and radiation dose adjustment, RP will eventually progress into pulmonary fibrosis and further worsen the patient's health. Therefore, early detection and intervention for RP is extremely important. Currently, diagnosis of RP is mainly symptom-dependent<sup>(9-11)</sup>, meaning that treatment is only available for patients whose

RP has already progressed enough for them to become symptomatic. The identification of individuals who are at high risk for developing RP through the use of an effective early predictor will be critical to reduce the incidence and extent of RP.

Based on the molecular and cellular changes that occur during the pathogenesis of RP<sup>(12,13)</sup>, a few molecules have been proposed as potential predictors for RP, such as inflammatory cytokines<sup>(14,15)</sup> and serum surfactant protein D (SP-D)<sup>(1)</sup>, in addition to others. However, further research is required to determine the clinical value of these molecular predictors<sup>(16)</sup>. In addition, although the ways in which certain inflammatory cells that are polarized in irradiated lungs contribute to the pathology of RP have been well studied, it remains unclear if

these cells have any predictive value for RP.

Neutrophils, a subset of granulocytes, are recognized as one of the major cell types involved in acute inflammation<sup>(14,17-19)</sup>. The increased number of neutrophils in bronchoalveolar lavage (BAL) fluid plays a critical role in the development of RP, which is due, in part, to the tissue damage caused by specific neutrophil degranulation products such as neutrophil elastase (NE)<sup>(20,21)</sup>. Additionally, monocytes and macrophages present in BAL fluid also contribute to the progression of RP<sup>(14)</sup>, likely due to the increased production of tumor necrosis factor-alpha (TNF- $\alpha$ )<sup>(22)</sup>, reactive oxygen species (ROS) and nitric oxide (NO)<sup>(23-25)</sup>, in addition to other products. Accordingly, it is reasonable to hypothesize that inflammatory CD45<sup>+</sup>HIS48<sup>+</sup> granulocytes<sup>(26,27)</sup> and CD45<sup>+</sup>CD11b/c<sup>+</sup>HIS48<sup>-</sup> monocytes/macrophages<sup>(28-32)</sup> could serve as potential predictive indicators of RP. The markers on these cells include CD45, which is a leukocyte common antigen (L-CA) expressed on all classic immune cells<sup>(33,34)</sup> and HIS48 and CD11b/c, which are markers of inflammation-associated granulocytes and monocytes/macrophages, respectively.

Unfortunately, the procedure for collecting BAL fluid is complicated and has a poor patient compliance. Accordingly, it would be difficult to achieve widespread clinical application if granulocytes and monocytes/macrophages obtained from BAL fluid were used as indicators. Since blood collection and subsequent testing is more convenient for both healthcare providers and patients, we sought to analyze changes in circulating granulocytes and monocytes/macrophages after radiation as well as their correlation with RP, and to explore their feasibility as RP predictors. The work presented here will be useful for determining an optimal early RP predictor, which will benefit patients and has the potential for widespread clinical use.

## MATERIALS AND METHODS

### Materials and animals

Alexa Fluor<sup>®</sup> 647 Mouse Anti-Rat CD45 Clone OX

402

-1, FITC Mouse Anti-Rat Granulocytes Clone HIS48 and Lysing Buffer were obtained from BD Bioscience (US). Anti-CD11b/c antibody [OX42] (ab1211) was obtained from Abcam (UK). Sodium pentobarbital and ethylenediaminetetraacetic acid (EDTA) dipotassium salt were purchased from Sigma (US). All other reagents were purchased from China National Pharmaceutical Group Corporation (China).

SD rats (male, 10-11 weeks old, ~180 g) were obtained from the Laboratory Animal Center of Qingdao Institute (China) and housed under specific pathogen-free conditions. All animal studies were conducted in accordance with guidelines from the Laboratory Animal Management and Welfare Ethics Committee [Approval Reference NO. F2016001].

### Establishment of the RP rat model

A total of 24 SD rats were randomly assigned into the control and RP groups. For the RP group, RP was developed via chest radiation. Briefly, rats were fasted for 8 h and anaesthetized through intraperitoneal injection of 2% sodium pentobarbital at a dose of 40 mg/kg prior to radiation. Selective irradiation of the thoracic region was performed at a dose of 20 Gy<sup>(35-39)</sup> using a Varian Clinac 21EX accelerator (US) at a dose-rate of 400 MU/min. At 2 and 4 weeks post-radiation, rats were processed to harvest blood samples from the abdominal aorta for flow cytometry and lungs for HE staining.

### Flow cytometry

100  $\mu$ L of blood samples were stained for 30 minutes at 4°C with fluorescent antibodies. Red blood cells were lysed with 2 mL Lysing Buffer for 10 minutes at room temperature. Cells were then washed during a 5-minute centrifugation at 2000 rpm, resuspended in 200  $\mu$ L of PBS (pH 7.4) and filtered using a 100-mm strainer before analysis using a FACSaria II flow cytometer (BD Biosciences, US). Samples that had not been stained were used as the blank control. HIS48<sup>+</sup> and CD11b/c<sup>+</sup>HIS48<sup>-</sup> populations were gated on the basis of the CD45<sup>+</sup> cells. Data analysis was performed using Flowjo7.6.1.

### Statistical analysis

A Student's *t*-test was used to compare two

*Int. J. Radiat. Res., Vol. 19 No. 2, April 2021*

groups when normality and homogeneity of variance assumptions were satisfied. Otherwise, a non-parametric test was applied. Statistical tests were performed using SPSS17.0. A P value of 0.05 was used as the threshold for statistical significance.

## RESULTS

### **Successful establishment of the RP model**

A number of studies have shown that rat RP models can be successfully built using a radiation dosage of 20 Gy<sup>(35-39)</sup>. Consistent with these reports, rats in radiation groups developed RP, and no accidental deaths occurred throughout the course of the experiment. Histopathological changes in the lungs could be observed using HE staining (figure 1). At 2 weeks post-radiation we observed an increase in the infiltration of neutrophils, macrophages and lymphocytes, thickening of alveolar and vascular endothelium, edema and erythrocytic and fibrinous inflammatory exudates, all of which are clear signs of inflammation and are indicative of the development of RP (figure 1, c). Although the inflammation appeared to subside to some extent by week 4 (figure 1, d), significant pathological changes were still visible. In contrast, the control group displayed normal lung histology throughout the course of the experiment (figure 1, a & b).

### **Radiation induces an increase in CD45<sup>+</sup>HIS48<sup>+</sup> granulocytes in rat peripheral blood**

Because animal models have been shown to be in the early stage of RP around 2-4 weeks

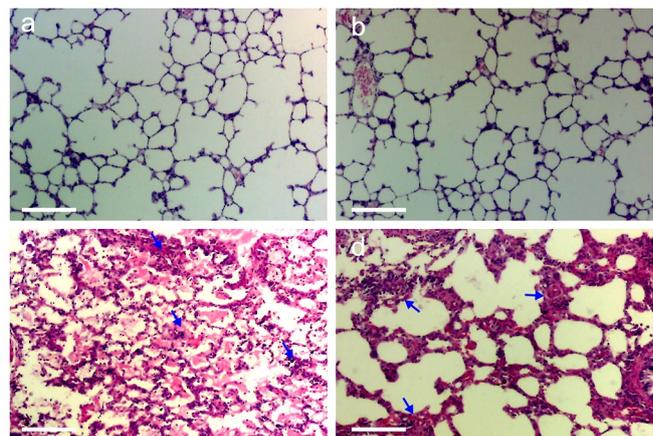

after irradiation<sup>(40,41)</sup>, we investigated changes in circulating inflammatory cells in rats at 2 and 4 weeks post-radiation. Using flow cytometry, leukocytes stained with anti-CD45 were first gated from total blood cells. Based on this, the two inflammation-associated subsets, granulocytes expressing HIS48 and monocytes/macrophages expressing CD11b/c were gated and analyzed.

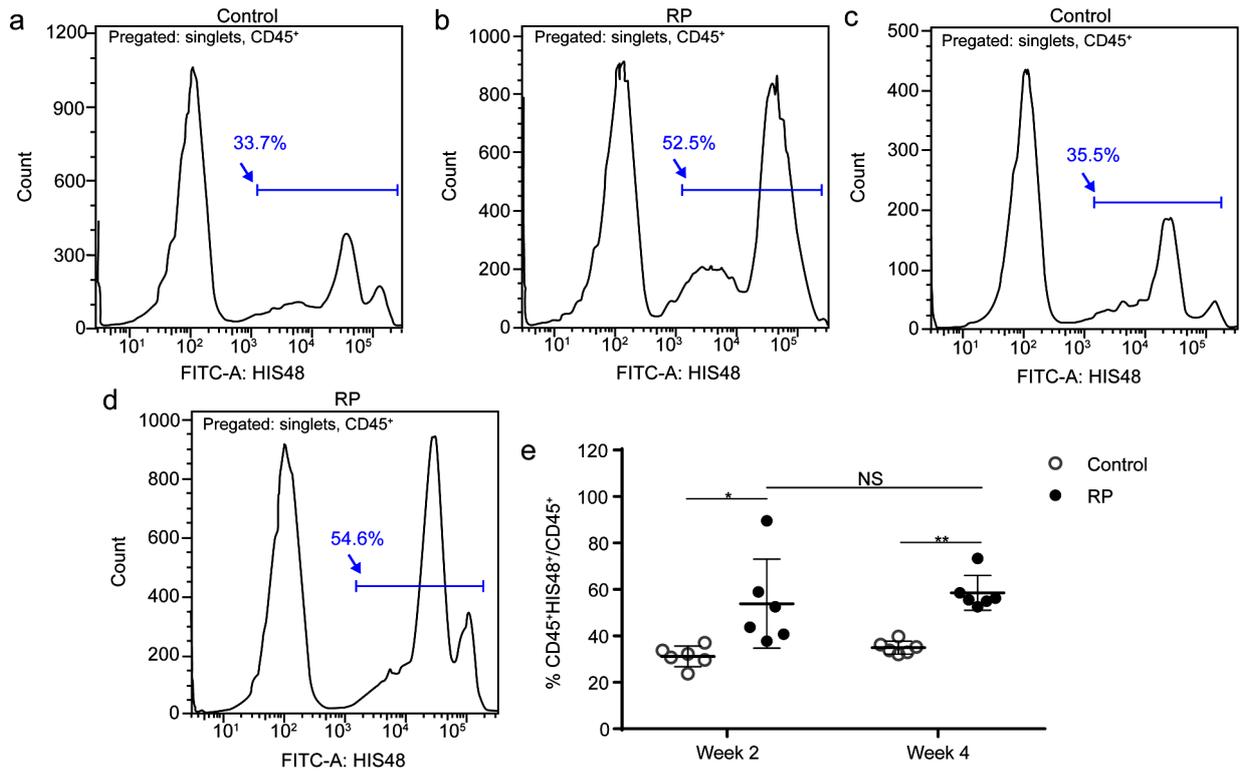

Analysis of the CD45<sup>+</sup>HIS48<sup>+</sup> population (figure 2 a-d, quantified in figure 2 e) showed that at 2 weeks post-radiation, 31.01±1.90% and 53.88±7.80% of the CD45<sup>+</sup> cells were HIS48<sup>+</sup> granulocytes in the blood of control and RP rats, respectively. This result indicates that thoracic radiation led to a significant increase in the amount of peripheral granulocytes in the blood within two weeks (P<0.05). Notably, the level of CD45<sup>+</sup>HIS48<sup>+</sup> granulocytes seemed to have plateaued by week 2 in RP rats, as the cell count at week 4 (58.62±8.60% CD45<sup>+</sup>HIS48<sup>+</sup> cells) showed only a minor increase which did not reach statistical significance (P>0.05).

### **Analysis of CD45<sup>+</sup>CD11b/c<sup>+</sup>HIS48<sup>-</sup> monocytes/macrophages in rat peripheral blood**

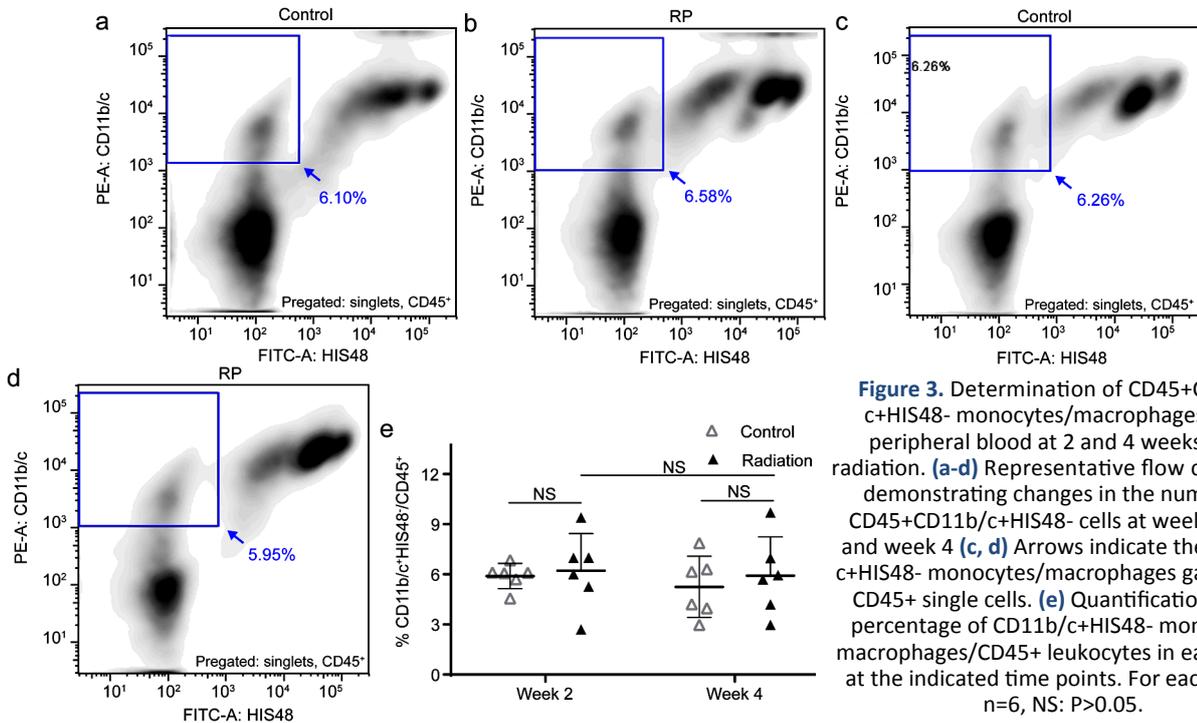

The second predictive indicator investigated was CD45<sup>+</sup>CD11b/c<sup>+</sup>HIS48<sup>-</sup> monocytes/macrophages. However, as shown in figure 3, unlike granulocytes, radiation did not induce an increase of CD45<sup>+</sup>CD11b/c<sup>+</sup>HIS48<sup>-</sup> cells at week 2 (figure 3, a, b and e) or week 4 (figure 3, c, d and e). The levels of CD45<sup>+</sup>CD11b/c<sup>+</sup>HIS48<sup>-</sup> cells were approximately 5% in each group, with no statistically significant difference found between the control and RP groups (P>0.05).

**Figure 1.** HE staining of lung tissues. (a, b) HE staining of lung sections obtained from the control group at week 2 (a) and week 4 (b). (c, d) HE staining revealing lung inflammation in irradiated rats (RP group) at week 2 (c) and week 4 (d) following radiation. Arrows indicate areas of inflammation. Magnification: ×400, scale bars: 100 μm.

**Figure 2.** Determination of CD45+HIS48+ granulocytes in rat peripheral blood at 2 and 4 weeks post-radiation. (a-d) Representative flow cytograms demonstrating changes in the number of CD45+HIS48+ cells at week 2 (a, b) and week 4 (c, d). Arrows indicate HIS48+ granulocytes gated from pre-gated CD45+ single cells. (e) Quantification of the percentage of CD45+HIS48+ granulocytes in pre-gated CD45+ leukocytes in each group at the indicated time points. For each group, n=6, NS: P>0.05, \*P<0.05, \*\*P<0.01.

**Figure 3.** Determination of CD45+CD11b/c+HIS48- monocytes/macrophages in rat peripheral blood at 2 and 4 weeks post-radiation. (a-d) Representative flow cytograms demonstrating changes in the number of CD45+CD11b/c+HIS48- cells at week 2 (a, b) and week 4 (c, d). Arrows indicate the CD11b/c+HIS48- monocytes/macrophages gated from CD45+ single cells. (e) Quantification of the percentage of CD11b/c+HIS48- monocytes/macrophages/CD45+ leukocytes in each group at the indicated time points. For each group, n=6, NS: P>0.05.

## DISCUSSION

It is well known that the increase of BAL fluid granulocytes, one of the biological responses induced by radiation, promotes the progression of RP<sup>(42-44)</sup>. However, our understanding of the correlation between peripheral granulocytes and RP is limited. Here, we show that radiation in rats led to an increase in peripheral granulocytes within two weeks (the early stage of RP). This finding is consistent with a previous report which showed that peripheral neutrophil counts increased over time in patients who ultimately experienced RP<sup>(45)</sup>, indicating that peripheral CD45+HIS48+ granulocytes may be clinically relevant and could serve as a valuable potential predictor of RP. However, the ways in which peripheral granulocytes contribute to the development of RP requires further exploration.

Prior studies also have established the importance of monocytes/macrophages in RP development<sup>(44, 46, 47)</sup>. Monocytes/macrophages induce toxic effects through the secretion of cytokines, interleukins, interferons, and NO<sup>(48)</sup> and the polarization of macrophages in lung tissue has been observed in RP samples<sup>(1, 49)</sup>. However, our work indicates that significant, systemic changes of macrophages does not occur during RP development. It is possible that this is because inflammation-associated macrophages were recruited and function locally, leading to a relatively minor change in peripheral blood. An investigation conducted in patients noted an increase in alveolar macrophages in bronchoalveolar lavage fluid, not serum, providing support for this possibility<sup>(1)</sup>. Moreover, as revealed by our work, under normal physiological conditions, monocytes/macrophages only account for ~5% of peripheral CD45+ cells analyzed, whereas granulocytes represent ~30%. The possible insensitivity of flow cytometry when analyzing this small cell population may mask minor changes in macrophage content.

Taken together, this article provides evidence supporting the potential use of peripheral CD45+HIS48+ granulocytes as an early predictor of RP. The proposed indicator can easily be

tested in clinics, requiring only two simple processes: a routine blood sample collection and flow cytometry analysis.

## CONCLUSION

A significant increase in peripheral CD45+HIS48+ granulocytes was observed at the early-stage of RP in rats, suggesting the potential value of these cells in predicting the development of RP. This potential predictor can be detected in the blood, which facilitates sample collection for both patients and doctors, and therefore offers significant promise for widespread clinical application.
