Department of ultrasound, the fourth hospital of Shijiazhuang City, Hebei Province, 050000, China

ABSTRACT

Background: To explore the efficiency of transvaginal ultrasonography in determining muscular infiltration of phase I endometrial cancer prognosis for radiotherapy. **Materials and Methods:** A total of 96 phase I endometrial cancer patients who were admitted between March 2018 and March 2020 were enrolled and transvaginal ultrasonography was applied for the diagnosis of muscular infiltration. Demographic variables and radiotherapy outcomes were recorded. We hypothesized that only patients with unfavorable profile of sonography receive pelvic radiotherapy. **Results:** Patients with muscular infiltration $> 1/2$ had much thicker endometrium than those with muscular infiltration $\leq 1/2$. The sensitivity, specificity, accuracy, positive predictive value and negative predictive value of transvaginal ultrasonography in diagnosis of muscular infiltration of phase I endometrial cancer versus surgery results were 84.9%, 88.9%, 87.5%, 80.0% and 91.8%, while the consistency and Kappa value between the transvaginal ultrasonography and pathological test was 72.2% and 0.580. Positive Likelihood ratio of muscular infiltration more than $1/2$ was 2.10 (CI95%: 1.22 to 3.61), meaning that approximately 10 patients of 17 patients with muscular infiltration more than $1/2$ would experience radiotherapy later. Negative Likelihood ratio was 0.63 (CI95%: 0.44 to 0.91), meaning that approximately 10 patients of 15 patients with muscular infiltration less or equal than $1/2$ would not experience radiotherapy later. **Conclusion:** Muscular infiltration of endometrial cancer in transvaginal ultrasonography could be a reliable, simple, convenient and low-cost method predicting the need for the external beam pelvic radiotherapy as an unfavorable progression in endometrial cancer.

Keywords: Transvaginal ultrasonography, endometrial cancer, phase I, muscular infiltration.

INTRODUCTION

Endometrial cancer, as a kind of endometrial epithelial malignant tumor, ranks the third in the tumor-related mortality rate in the tumors of female reproductive system, only lower than the ovarian cancer and cervical cancer ⁽¹⁾. Peri- and post-menopause women are the high-risk population of endometrial cancer, and the clinical prevalence of endometrial cancer presents with the evident trend of increase. Current evidence has shown that early diagnosis

and treatment can remarkably improve the efficacy, and appropriate, in-time treatment could increase the 5-year survival rate of patients to 80% ⁽²⁾. Hence, early diagnosis and the appropriate, in-time surgical treatment are quite important to the patients. Though uterus curettage is one of the options for diagnosis of endometrial cancer, it fails to reflect the range and depth of lesions ⁽²⁾. Magnetic resonance imaging (MRI), though it can reflect the degree of muscular infiltration in uterus, has also been limited in the application due to the high

expense ⁽³⁾. Transvaginal ultrasonography can display the size of infiltrated lesions and the Doppler indicators of the local lesions, while the depth of muscular infiltration affects directly the prognosis of endometrial cancer patients, so it is necessary to measure the depth of muscular infiltration prior to the surgery ⁽⁴⁾.

Previous studies have used molecular methods to determine the need for the radiotherapy. Based on the PORTEC-3 trial, patients with stages II and III and high-risk stage I endometrioid endometrial cancer would need radiation ⁽⁵⁾. Also, plenty studies have conducted to demonstrate the imaging characteristics of each stage of this cancer. High-risk lesions were less prone to have normal endometrial-myometrial junction, larger, and more probable to have non-uniform echogenicity compared to low-risk tumors ⁽⁶⁾. This would be easy for clinicians to decide radiotherapy initiation in high-grade cancers; but, at early stages, the decision would be doubtful.

Based on the PORTEC-2 trial, patients with stage 1C grade 1/2, or 1B grade 3 cancer were included in study. They randomly assigned patients to groups receiving external beam radiotherapy or vaginal brachytherapy ⁽⁷⁾ and there were no definitive criteria to assign patients for these treatments. While imaging studies could be used to assess the response rate to various treatments as those are reflections of the pathological findings of the tumor; there is no such progression risk analysis based on the imaging methods even before surgery. Thus, in this study, we investigated the efficiency of transvaginal ultrasonography in diagnosis of the depth of muscular infiltration of phase I endometrial cancer and its association with the later occurrence of a radiotherapy, and the detailed information is reported as follow.

MATERIALS AND METHODS

General data

A total of 96 phase I endometrial cancer patients who were admitted to this hospital between March 2018 and March 2020 were enrolled into this study, and diagnosis was made

upon the results of pathological examination, represented based on the FIGO staging (Ia/ Ib/ Ic). All patients were informed of the content of this study and agreed to participate in this study, and this study had been approved by the Ethical Board of fourth hospital of Shijiazhuang. (Ethic registration number: EC-2018-9)

Inclusion criteria was phase Ia/ Ib/ Ic endometrial cancer diagnosed by pathology findings in patients who had a surgery for the tumor removal. Patients with the severe disorders in liver or kidney, or in lactation period were excluded from this study.

A Color Doppler Ultrasonography Device (GE730, General Electric, USA) was used in this study, with the frequencies of probe in the abdomen and vagina being set between 2 and 5 MHz and 5.0 and 7.5 MHz. In brief, abdominal ultrasonography was performed to detect the anomalies in uterine adnexa and pelvic cavity, and patients were then required to void the bladder for vaginal ultrasonography. Coupling agent was smeared on the vaginal probe that was coated by the condom, and then the probe was placed in the vagina for continuous scanning procedures by adjusting the direction and depth of probe. Myometrial depth of infiltration was determined by experienced expert to be lower or higher than 50% infiltration (figure 1).

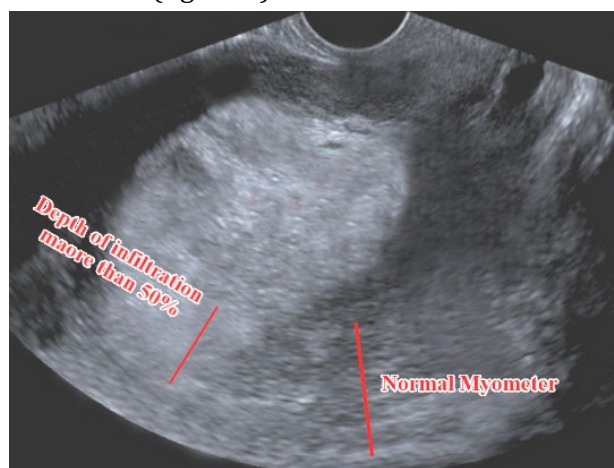

Figure 1. Myometrial depth of infiltration more than 50% Myometrial infiltration is shown in comparison of the normal view of the myometer with no infiltration.

46 Gy, with 2 Gy fractions, 5 times per week was prescribed as radiation therapy dosage for patients who were detected eligible based on the physicians decision (external beam radiotherapy machine, TSE: 6501, Hitachi Ltd. Japan).

Criteria for evaluation

Evaluation of muscular infiltration: Depth of infiltration refers to the thickness of normal muscular layer minus the depth of infiltrated lesion, and infiltration degree was presented with the ratio of infiltration depth to the thickness of normal muscular layer and categorized into three degrees – 0, $\leq 1/2$ and $> 1/2$.

For the criteria for evaluation of stage, phase Ia referred to the patients with complete uterine junction zone, or with complete enhanced zone of endometrium in enhancement scan, where the thickness of premenopausal endometrium > 10 mm or that of postmenopausal endometrium > 5 mm; phase Ib referred to patients with the interruption of uterine junction zone, or with coarse surface in enhancement scan, with the signals reaching to the muscular layer $\leq 50\%$; phase Ic referred to the patients with signals of tumor reaching to the muscular layer $> 50\%$.

We hypothesized that only patients with unfavorable profile of sonography receive pelvic radiotherapy and assessed the sonography sensitivity and specificity.

Statistical analysis

Patients' records were assessed for demographic variables and performance of an external beam pelvic radiotherapy based on the tumor characteristics. SPSS 21.0 software was utilized to perform the statistical analysis. Measurement data were shown in form of mean \pm standard deviation (SD), and the difference between two groups was validated by the *t* test. Enumeration data were shown in form of rate (%), and the difference between two groups was validated by the chi-square test. $P / 0.05$ suggested that the difference had statistical significance.

RESULTS

Patients aged between 34 and 59 years old, with an average age of (48.1 ± 2.3) years old. As for the distribution of clinical manifestations, there were 51 patients with postmenopausal irregular bleeding, 37 with bleeding in the reproductive age, 15 with the odor of vaginal secretions and 7 with no obvious symptoms. For the postoperative pathological examination, there were 25 patients in phase Ia, 33 in phase Ib and 38 in phase Ic. For the type of endometrial cancer, there were 21 patients with non-adenocarcinoma and 75 with adenocarcinoma.

Comparison of the basic condition of patients with different degrees of muscular infiltration

Patients with muscular infiltration $> 1/2$ had much thicker endometrium than those with muscular infiltration $\leq 1/2$. As the histological category escalated, proportion of patients with muscular infiltration $> 1/2$ also increased, while the proportion of those with muscular infiltration $\leq 1/2$ decreased evidently (all $P / 0.05$). Patients with the lymph node metastasis had a higher proportion of muscular infiltration $> 1/2$ than those with no lymph node metastasis, while the proportion of muscular infiltration $\leq 1/2$ was much lower (all $P / 0.05$). For patients with varying menopausal condition and pathological types, the proportions of patients with muscular infiltration $> 1/2$ or $\leq 1/2$ showed no significant difference ($P = 0.05$; table 1).

Analysis of the parameters of transvaginal ultrasonography in evaluation of the muscular infiltration in phase I endometrial cancer

The sensitivity, specificity, accuracy, positive predictive value and negative predictive value of transvaginal ultrasonography in diagnosis of muscular infiltration of phase I endometrial cancer were 84.9% (28/33), 88.9% (56/63), 87.5% (84/96), 80.0% (28/35) and 91.8% (56/61) (table 2).

Table 1. Comparison of the basic condition of patients with different degrees of muscular infiltration [n (%)].

Clinical features		Muscular infiltration > 1/2 (n = 33)	Muscular infiltration ≤ 1/2 (n = 63)	t/c ²	P
Thickness of endometrium (mm, mean ± SD)		31.1±5.3	20.2±3.4	3.91	<0.05
Condition of menopause	Menopausal	23(41.1)	33(58.9)	1.48	>0.05
	Non-menopausal	11(27.5)	29(72.5)		
Pathological types	Adenocarcinoma	24(32.0)	51(68.0)	0.76	>0.05
	Non-adenocarcinoma	9(42.9)	12(57.1)		
Histological grades	G1	8(14.0)	49(86.0)	21.68	<0.05
	G2	14(60.9)	9(39.1)		
	G3	12(75.0)	4(25.0)		
Lymph node metastasis	Yes	11(73.3)	4(26.7)	8.28	<0.05
	No	22(27.2)	59(72.8)		

Table 2. Analysis of the parameters of transvaginal ultrasonography in evaluation of the muscular infiltration in phase I endometrial cancer (n).

Transvaginal ultrasonography	Muscular infiltration		
	>1/2	≤1/2	Total
>1/2	28	7	35
≤1/2	5	56	61
Total	33	63	96

Analysis of the consistency in diagnosis of phase I endometrial cancer with transvaginal ultrasonography and pathological

According to the analysis, the consistency and Kappa value between the transvaginal ultrasonography and pathological test was 72.2% and 0.580 (table 3).

Radiotherapy receiving outcome

Considering the Muscular infiltration more than 1/2 positive for Transvaginal ultrasonography and Muscular infiltration ≤1/2 as negative, the Likelihood of the need for external beam pelvic radiotherapy was assessed. Based on the results, 21 patients who had Muscular infiltration >1/2, and 19 patients with muscular infiltration ≤1/2, received external beam pelvic radiotherapy (table 4).

Based on the table 5 and figure 2, Positive Likelihood ratio was 2.10 (CI95%: 1.22 to 3.61). Negative Likelihood ratio was 0.63 (CI95%: 0.44 to 0.91).

Table 3. Analysis of the consistency in diagnosis of phase I endometrial cancer with transvaginal ultrasonography and pathological (n).

Transvaginal ultrasonography	Pathological stages			
	Ia	Ib	Ic	Total
Ia*	17	8	0	25
Ib*	5	24	4	33
Ic*	3	7	28	38
Total	25	39	32	96

Note: according to FIGO staging Ia shows that tumor limited to one ovary; capsule intact, no tumor on ovarian surface; no malignant cells in ascites or peritoneal washings, Ib shows that Tumor limited to both ovaries; capsules intact, no tumor on ovarian surface; no malignant cells in ascites or peritoneal washings and Ic shows that tumor limited to one or both ovaries with any of the subcategories below.

Table 4. Positive and negative transvaginal ultrasonography vs. Radiotherapy occurrence.

Transvaginal ultrasonography for Muscular infiltration	External beam pelvic radiotherapy		
	yes	no	Total
>1/2	21	14	35
≤1/2	19	42	61
Total	40	56	96

Table 5. Likelihood ratio of test.

	Value	95% CI
Positive Likelihood ratio	2.10	1.22 to 3.61
Posterior probability of Positive test (odds)	60% (1.5)	47% to 72%
Negative Likelihood ratio	0.63	0.44 to 0.91
Posterior probability of Negative test (odds):	31% (0.5)	24% to 39%

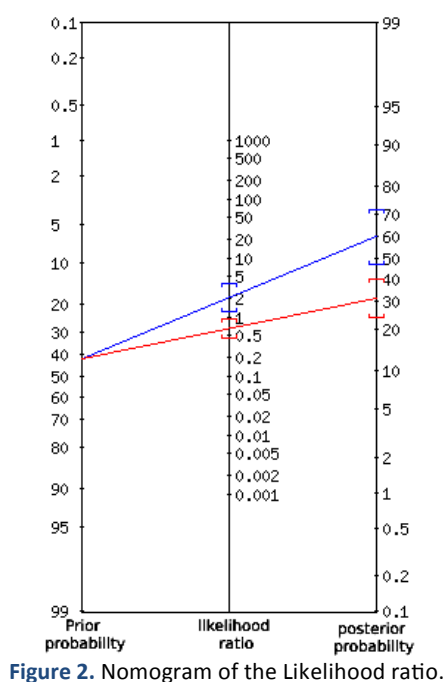

Figure 2. Nomogram of the Likelihood ratio.

In this nomogram, the left, middle, and right axes represent the pre-test probability, likelihood, and post-test probability, respectively. To use this nomogram, the pre-test and likelihood probabilities in the left and middle axes get marked (left side). Then a straight line from the mark on the left axis to the mark on the middle axis and extended to the line to the right axis is drawn. The location of the intersection of this line and the axis on the right will indicate the probability after the test. Meaning that approximately 10 patients of 15 patients with muscular infiltration less or equal than $\frac{1}{2}$ would not experience radiotherapy later and approximately 10 patients of 17 patients with muscular infiltration more than $\frac{1}{2}$ would experience radiotherapy later.

DISCUSSION

While some scholars believe that in the early stage of endometrial cancer, patients present with the normal result in ultrasonography, with no evident enlargement in uterus, so ultrasonography is only suitable for patients with tumor invasion into the muscle layer (8-10). Nearly half of the endometrial cancer patients

are diagnosed in the postmenopausal period, with the major clinical manifestation of vaginal bleeding. As the prevalence of endometrial cancer increases, a method that can reflect the phase of endometrial cancer is of great significance for the rational evaluation of prognosis and appropriate treatment (11). Especially for patients with phase I endometrial cancer, accurate evaluation of the infiltration depth of tumor into the muscle is key to the selection of surgical methods.

As reported, no muscular infiltration and the specified infiltration depth into the muscular layer should be taken as the criteria for evaluating the phase, where patients in phase Ia have tumors in the endometrium, with no infiltration into the muscular layer, patients in phase Ib have tumors that infiltrate into the superficial layer of muscle ($\leq 50\%$), and those in phase Ic have tumor infiltrating into the deep layer of muscle ($>50\%$) (12). Moreover, the varying degrees of muscular infiltration in the endometrial cancer patients affect the efficacy and the risk of lymph node metastasis, where patients in phase Ia usually are free from the lymph node metastasis, patients in phase Ib have incidence rate of 30% in lymph node metastasis and those in phase Ic have incidence rate of over 50% in lymph node metastasis (13). Besides, patients with the muscular infiltration have a significant increase in the recurrence rate even though they receive the appropriate therapy. Therefore, early diagnosis and appropriate treatment could maximize the survival time of patients.

Our study showed that approximately 10 patients of 15 patients with muscular infiltration less or equal than $\frac{1}{2}$ would not experience radiotherapy later after the surgery. Also, 10 patients of 17 patients with muscular infiltration more than $\frac{1}{2}$ would experience radiotherapy later. Previous studies had attempts to predict the need for radiotherapy based on the molecular characteristics of the tumor. Unfavorable profile of endometrial cancer which needs external beam pelvic radiotherapy was defined by van den *et al.* (14). Molecular-integrated risk profile was suggested by Wortman *et al.* also confirmed the worse

condition of the patient and the need for the radiotherapy. This was also confirmed in our study; while we used sonography-integrated risk profile ⁽¹⁵⁾.

MRI is believed to be an efficient tool in evaluating the muscular infiltration, but due to the high expense, a great number of patients have to give up this choice. Transvaginal ultrasonography possesses many advantages, including the simple, convenient and repeatable operation, high resolution, no invasion, low cost and immunization from the effect of obesity and intestinal gas ⁽¹⁶⁾. Besides, the multi-frequency probe can display the ovary, uterus and the adjacent tissues of patients clearly, while color ultrasonography can reflect the changes in the hemodynamics of patients, in which the resistance of blood flow can be demonstrated by the change in the frequency spectrum. Thus, color doppler ultrasonography in combination with the uterine curettage is the major way for diagnosis of endometrial cancer ⁽¹⁷⁾.

Transvaginal ultrasonography is a kind of non-invasive technique, and the high-resolution probe can display the structure of uterus, identify the muscular layers and endometrium precisely and evaluate the muscular infiltration of patients, thus providing solid evidence for the staging of endometrial cancer. In the diagnosis of phase I endometrial cancer, transvaginal ultrasonography is the first choice for preoperative examination ⁽¹⁸⁻¹⁹⁾.

In this study, we found that patients with muscular infiltration $>1/2$ had much thicker endometrium than those with muscular infiltration $\leq 1/2$. As the histological category escalated, proportion of patients with muscular infiltration $>1/2$ also increased, while the proportion of those with muscular infiltration $\leq 1/2$ decreased evidently (all $P/0.05$). Patients with the lymph node metastasis had a higher proportion of muscular infiltration $>1/2$ than those with no lymph node metastasis, while the proportion of muscular infiltration $\leq 1/2$ was much lower (all $P/0.05$).

For patients with varying menopausal condition and pathological types, the proportions of patients with muscular

infiltration $>1/2$ or $\leq 1/2$ showed no significant difference ($P=0.05$). Besides, the sensitivity, specificity, accuracy, positive predictive value and negative predictive value of transvaginal ultrasonography in diagnosis of muscular infiltration of phase I endometrial cancer were 84.9%, 88.9%, 87.5%, 80.0% and 91.8%, while the consistency and Kappa value between the transvaginal ultrasonography and pathological test was 72.2% and 0.580. These findings are consistent with the previous results ⁽²⁰⁾.

In another study, Yela *et al.* showed that in postmenopausal patients, ultrasonography has a sensitivity of 99.0%, specificity of 19.0%, PPV of 96.1%, NPV of 50.0%, and accuracy of 95.3%, and in contrast, hysteroscopy has a sensitivity of 96.7%, specificity of 86.9%, PPV of 99.2%, NPV of 58.8%, and accuracy of 96.2% ⁽²¹⁾. However, in the present study, we examined bedside sensitivity.

Mohammad *et al.* conducted a study comparing the diagnostic power and sensitivity of three-dimensional and hysteroscopic transvaginal ultrasound in the diagnosis of intrauterine lesions. In their study The reliability, precision, positive predictive value, negative predictive values and cumulative overall accuracy of Three-dimensional transvaginal ultrasound for total irregular outcomes was 89.13 %, 100 %, 100 %, 44.44 % and 90 %, respectively, compared with the use of hysteroscopy ⁽²²⁾. In line with the results of our study, the results of Mohammad *et al.* study also show the high sensitivity of ultrasound in the diagnosis of intrauterine lesions.

In another study 255 patients with irregular uterine bleeding by ultrasound, sonohysterography and operative hysteroscopy were examined by El Tabbakh *et al.* Histological examination revealed endometrial hyperplasia in 70 patients where sensitivity, specificity, positive predictive value, negative predictive value and diagnostic accuracy were 77%, 94.6%, 84.4%, 91.6% and 89.8% for transvaginal ultrasound and 95.7%, 96.8%, 91.8%, 98.35% and 96.5% for sonohysterography ND 75.7%, 97.3%, 91.4%, 91.45%, 91.4% for hysteroscopy ⁽²³⁾.

CONCLUSION

Overall, Muscular infiltration of phase I endometrial cancer in transvaginal ultrasonography could be assumed as an indicator of radiotherapy requirement after surgery in endometrial cancer research. Further studies in clinical trials would help to determine the benefits of taking muscular infiltration into account as an indication of radiotherapy. But, this approach for predicting the need for the external beam pelvic radiotherapy as an unfavorable progression in endometrial cancer is simple, convenient and low-cost.

Conflicts of interest: Declared none.
